This work was performed under task AM-D-92-HRR-141 and Contract No. 91-C-91089.

Abstract

In the United States, flight data are represented on a paper Flight Progress Strip (FPS). The role of the FPS has recently attracted attention because of plans to automate this aspect of air traffic control. The communication activities and FPS activities of air traffic controllers were categorized while they controlled air traffic of varying complexity. Transition networks were derived from the empirical transitions. These networks indicated that several aspects of air traffic control generalize across complexity, including the centrality of writing-on-the-FPSs to the control of traffic. Complexity was a factor when FPSs were used with high complexity traffic situations, requiring the controller to direct uninterrupted periods of time to the management of the FPSs rather than integrating these board management responsibilities with the responsibilities of separating aircraft.
ACKNOWLEDGMENTS

O. U. Vortac represents the collaborative research efforts of Francis T. Durso, Scott D. Gronlund, and Stephan Lewandowsky of the Department of Psychology at the University of Oklahoma, Norman, OK 73019-0535, USA. We wish to thank Gwen Sawyer, Manny Torres, Claude J. Schuldt, and Tom Lynch, all of the FAA Academy in Oklahoma City, for their help, and Cornelia Rea of the University of Oklahoma for her assistance.

We also thank the following people for their insightful comments: Bob Blanchard, William Collins, Pam Della Rocco, Ron Lofaro, Richard Mogford, Betty Murphy, Dave Schroeder, Michael Wayda, and Hilda Wing.

EN ROUTE AIR TRAFFIC CONTROLLERS’ USE OF FLIGHT PROGRESS STRIPS: A GRAPH-THEORETIC ANALYSIS

BACKGROUND

In the United States, en route air traffic control (ATC) of high-speed and high-altitude aircraft traveling between airports, is currently accomplished with three tools: the radar, communication devices (radio and telephone), and a representation of flight information. Flight information is displayed on a flight progress strip (FPS), a rectangular piece of paper divided into 31 logical fields, each of which displays particular information available from the flight plan. When a flight enters the volume of airspace (sector) for which a controller is responsible, the flight is considered active, and the controller moves the corresponding strip from a suspend bay where the imminent entries to the sector are held to the active bay; thereafter the controller interacts with the corresponding FPSs by moving the strips within the active bay, by writing on the strip itself, and by looking at the strip to acquire or confirm flight information. The organization and upkeep of the suspend bay and the active bay is referred to as board management.

The responsibility for board management depends on the number of controllers assigned to control a sector. When a sector is handled by a team of two, the “R” (radar) controller is primarily responsible for observing the radar screen and for talking to the pilot, whereas the “D” (data) controller (sometimes called the radar associate), seated next to the R-side controller and in front of the strip bays, is usually responsible for the FPSs. On several occasions, traffic loads permitting, both functions are frequently assigned to one controller, as they were in the study described here. This requires the controller to integrate board management with aircraft separation responsibilities.

This research focused on the FPS for two major reasons. First, although controllers must use FPSs to maintain a legal record of control actions as dictated by the ATC Handbook 7110.65, it is otherwise unclear why or when the controller uses the FPSs. Anecdotes from controllers often support the notion that the FPS is viewed as unimportant. This perceived lack of importance was reinforced by the results of a structured interview conducted by Human Technology Inc. (1990). Controllers were asked about their priorities of activities under normal workloads. On a scale of 1 to 9 (9 being lowest priority), experts gave Reviewing FPSs a 6.0 and Writing on FPSs an 8.8.

On the other hand, observers of the air traffic control situation have advanced compelling arguments that the FPS, even if used only because of legal requirements, may provide coincidental, but substantial, benefits to the controllers (e.g., Hopkin, 1988; Means, Mumaw, Roth, et al., 1988; see Vortac & Gettys, 1990, for a review). Hopkin believes that the relatively effortless incidental encoding of flight data which results from following the legal requirements helps to build understanding and memory. For example, when an aircraft is given a new speed, the old speed is crossed out and the new speed written on the strip (Weston, 1983), making the strip more distinctive and presumably easier to locate and remember. Finally, it is clear that not all the interaction with the strips is legally required. For example, the controllers may offset a strip from the bay as a reminder to take a future action.

A second reason to focus on the FPS is that the nation’s air traffic control system will undergo a period of radical and unprecedented change in the next decade. The Advanced Automation System (AAS), to be phased in during the 1990s, will have substantial ramifications for all aspects of air traffic control (e.g., Ammerman & Jones, 1988). The first stage of AAS in the en route environment involves introduction of the Initial Sector Suite System (ISSS). The area of greatest change due to ISSS involves the way in which flight information is displayed and manipulated. The paper FPS will be replaced by electronic Flight Data Entries. It is the automation of the FPS that has attracted the attention of aviation psychologists. If the introspections of controllers are correct, then the automation of the strips will make little or no difference. If these introspections are
incomplete or incorrect, and the observations offered by human factors experts turn out to be true, automation could have a substantial impact.

Unfortunately, little empirical evidence is available that details when FPSs are typically used. Work by Standard Technology Inc. (1990) suggests that FPS usage does not bear a simple relationship to air traffic complexity. Although strip activity was weakly predicted by the time aircraft spent in a sector for the two-controller situation, no scenario characteristic was predictive of strip activity for the one-controller situations. Nevertheless, other actions taken by the air traffic controller (for example, the commands he or she issues) and other types of information received by the air traffic controller (for example, communications from aircraft and other ATC facilities) may illuminate ways in which the FPSs are used.

For example, Buckley, DeBaryshe, Hitchner, and Kohn (1983) measured some 28 potential indices of ATC system performance, including a variety of behavioral measures as well as various radar-related (Plan View Display) indices (e.g., aircraft separation, time under control for each aircraft, etc.). A factor analysis revealed that a set of four factors could account for most of the variance between scenarios of different complexity. Three of these factors (labeled confliction, occupancy, and delay) summarized the PVD-related technical measures and are difficult to observe, whereas the fourth factor (communication) subsumed behaviors of the controller. Thus, looking at the relationship between communication events and FPS activities seems an appropriate first step.

The goal of this study was to understand better when controllers currently use FPSs to control traffic in an en route environment. Potential implications of automation (Wise, Hopkin, & Smith, 1991) can only be assessed in comparison to a well-understood existing system. The present study is an observational study. The research focuses on data obtained from a sample of controllers who each worked individually, fulfilling both R and D functions. The data involve the on-line classification of communication events (i.e., controller commands, controller queries, pilot requests, and sector transitions) and FPS activities (i.e., looking at FPSs, writing on FPSs, and manipulating FPSs). These data were used to construct transition matrices which summarized, for example, how often a look at the FPSs was followed by a controller command.

However, attempts to determine the behavioral structure that underlies air traffic control from the raw transition matrices is unsatisfactory for at least two reasons. First, the transition matrices are quite complex. Second, and more important, the matrices do not distinguish between those transitions present in the data that reflect the latent structure of controlling air traffic and those present in the data because of random noise. What is needed is a way to reduce the complexity by eliminating those transitions that merely reflect noise in the data, so that the remaining transitions provide structural insights. By assuming that the underlying structure is a graph (in the mathematical sense), we can distinguish between those transitions that are necessary to the structure and those that are not.

A graph is a formalism in which the concepts (e.g., controller command) are represented by a node and the transitions (e.g., controller command to write on FPS) are represented by arcs connecting nodes. The graphs for these data should be directed (i.e., event A leads to event B) because the transition matrix is asymmetric. Thus, the proportion of transitions from write on FPS to look at FPS need not be the same as the proportion of transitions from look at FPS to write on FPS. If the arcs are weighted so that some arcs are traversed more frequently than others, the resultant formalism is a network.

One node can be connected to another in a network either directly, by an arc from that node to the other, or indirectly, by a path through other nodes. The simplest such network consists of only those paths between two nodes that are the most efficient (shortest) (see Schvaneveldt, Deatholt, & Durso, 1985). The representation of all such paths yields a network that represents the shortest distance between all pairs of nodes. This is important because this network will satisfy the triangle inequality: The distance from A to B plus the distance from B to C cannot be less than the distance from A to C. In most modern scaling procedures, violations of the triangle inequality are assumed to be due to random noise and distortions and not valid indicators of the underlying structure.
In an effort to reveal the underlying structure in our transition matrices, the Pathfinder scaling algorithm was selected (Schvaneveldt, 1990; Schvaneveldt & Durso, 1981; Schvaneveldt, Durso, & Dearholt, 1989). The Pathfinder analysis represents the relationships among events graphically so that the underlying structure in the transition matrix can be more readily interpreted. The algorithm reduces a matrix of proximity data (e.g., transitions) by eliminating those connections that do not satisfy the metric properties of a network. Thus, the connections remaining are those that are ordinarily necessary (Hutchinson, 1989).

The algorithm has been successfully employed in a variety of domains within cognitive psychology, engineering, and artificial intelligence (see Schvaneveldt, 1990). For example, Pathfinder has been used to articulate the structure of natural categories (Durso & Coggins, 1990), to distinguish between expert and novice fighter pilots (Schvaneveldt, Durso, Goldsmith, et al., 1985), to predict free recall (Cooke, Durso, Schvaneveldt, 1986), to develop menus for automated cockpits (Roskeh-Hofstrand & Paap, 1986), and to establish connections in hypertext (McDonald, Paap, & McDonald, 1990). The mathematical foundations can be found in Schvaneveldt, et al. (1985). They will not be reviewed here so the focus can remain on the interpretation of the data.

**METHOD**

**Subjects**

Nine full-performance-level (FPL) controllers participated. They had served as en route FPLs from 3.5 to 9.3 years (M = 5.7) and had last been in the field 2 to 16 months prior to their participation (M = 7.4). The study was conducted at the Radar Training Facility at the FAA’s Mike Monroney Aeronautical Center in Oklahoma City, which can provide high fidelity en route traffic simulations using the fictitious AERO Center airspace used in training. Because subjects had to be familiar with AERO Center, but naive to the particular selection of scenarios, FAA Academy instructors in the nonradar screen program were used.

**Scenarios**

All subjects were observed under low, medium, and high levels of complexity, according to a randomized counterbalancing schedule. Across subjects, numerous different scenarios were used. Therefore, conclusions drawn for a level of complexity are unlikely to be due to a particular scenario. We used existing scenarios as outlined in the FAA Academy Scenario Guide (FAA Publication #EIL-10a-2). The scenarios varied in complexity from 25% to 95%. Complexity was measured using the complexity worksheet found in the Instrucational Program Guide, (Appendix B, section 3, Phase 8A for nonradar). Complexity is computed in the following way: departures received 5 points; arrivals, en route aircraft needing a control action, emergencies, and radio failures each received 4 points; special flights received 3 points; en route flights not needing a control action received 2 points; and each additional coordination action (e.g., a point-out) received 1 point.

All but the most complex scenarios represented a level of traffic density that, in the field, could be handled by a single FPL controller. The high-complexity scenario was comparable to a situation in the field where a supervisor would provide or a controller might request a

*Table 1. Summary of Scenarios for Different Complexities*
“D” side controller to assist. Table 1 summarizes the scenarios used in this study.

**Behavioral Categories**

The onset of four types of communication events and three types of FPS activities were coded. Communication Events were categorized into *Controller Commands, Controller Queries, Pilot Requests*, and *Sector Transitions*. FPS activities were categorized into *Looking on an FPS, Writing on an FPS*, and *Manipulating FPSs*.

**Communication Events**

*Controller Command (CCOM)*

A controller command involved one or several of the following six sub-components: 1) change route, 2) change speed, 3) change altitude, 4) dispense information, 5) issue clearance, or 6) other.

*Controller Queries (CQUERY)*

A controller query was a controller-initiated request for information from the pilot. A controller query occurred whenever the controller asked a pilot to report: 1) aircraft speed, 2) altitude, 3) route, or 4) other. The “other” subcategory tended to be requests for a verification of aircraft call sign or characteristics (e.g., “heavy”).

*Pilot Request (PREQ)*

A pilot request was a pilot-initiated request of the controller. Six possible pilot requests were coded: 1) change in route, 2) speed, 3) altitude, 4) information, 5) clearance (direct clearance to destination), and 6) other. Some of the “other” requests concerned air-refueling, and so on.

*Sector Transitions (SECTOR)*

Another event of interest involved interactions between the controller and adjacent centers and other ATC facilities, in particular when aircraft are entering or exiting a sector. Three components were coded: 1) departures, 2) turnovers, and 3) initial contact. A departure was a communication initiated by another ATC facility, a turnover was initiated by the controller, and initial contact was initiated by the pilot. The distinction between PREQ category above and the *initial contact* subcategory of SECTOR was entailed in the content of the pilot’s communication.

In order to examine the relations between the events above and controller activities relating directly to the FPS, the following FPS activities were coded.

**FPS Activities**

*Write (WRITE)*

A WRITE was coded whenever the controller verified or changed an entry on an FPS. Verification involved one or more of the following four symbols: 1) “D” for departure, 2) “R” for radar contact, 3) a check mark when a new altitude was achieved, and 4) “C” for hand-off to the next sector. Change involved any other marking on the FPS, such as a revision of altitude or change in route.

*Manipulate (MANIP)*

The manipulation of an FPS was any physical contact with the strip that did not involve writing. Five categories of FPS manipulation were coded. These were: 1) moving a strip from the suspense to the active bay when a flight entered the airspace, 2) sequencing the strips within the active bay, 3) offsetting or “cocking” a strip as a reminder, 4) flattening or removing the offset, and 5) tearing down or removing the strip from the active bay when a flight leaves the airspace.

*Look (LOOK)*

A LOOK was coded whenever the controller looked at the suspense or the active bay. Because a look obviously precedes other FPS activities, this category only included those looks at the FPSs that were not immediately followed by writing or manipulating. Those events were instead coded as a WRITE or a MANIP. In addition, multiple LOOKS at the FPSs imply that the controller looked away (presumably to the radar display)
and returned to look at the FPSs. Thus, a long, single look at the FPSs, or a search through the strips, was coded as a single LOOK.

Procedure

Subjects first completed a brief background sketch. They were then given the opportunity to organize the strip bay in preparation for the scenario. Subjects were provided with all the strips for the problem at this time. In our situation, the strip bay was located to the right of the radar screen. The two observers sat behind and to the right and left of the controller, with notebook computers on their laps. The computers were used for on-line data collection. Both computers were synchronized with the clock on the radar screen, and observers coded behaviors by pressing different keystroke combinations as they occurred, yielding a time-indexed behavioral record of each scenario. Simultaneous events were codable, but appeared as sequences in the data trace. Coding errors could be corrected on-line by escaping from the submenus.

In addition to the observers, two ghost pilots were required to control the planes, and another assumed the communication functions of adjacent centers and other ATC facilities. Radio and audio communications were recorded using a multi-track cassette recorder. One input channel included communications of the controller, the pilots, and the center. Each observer wore a lapel microphone and was recorded on their own input channel, which allowed them to annotate orally their event-recording.

Subjects were not informed about the emphasis placed on FPSs in this study, but were told to control traffic normally. Each experimental session lasted approximately 3 hours (2 x 30-minute scenarios plus 1 hour for the most complex scenario). Break periods between scenarios were approximately 20 minutes.

RESULTS

Any coding errors committed by the observers that were noted on the tape were corrected prior to analysis.

Event rates

Events per minute were computed for each of the seven classes of events (See Figure 1). An ANOVA was conducted for each event class, with a test-wise α of .007 to yield an experiment-wise α of .05. As would be expected, the rate of sector transitions increased with complexity, $F(2,16)=23.88$, $MSe=.02$, $p<.0001$. The most frequent events, CCOM and WRITE, tended to occur at the same rate regardless of complexity. In fact,
the only other event to vary significantly with complexity was MANIP, \( F(2,16)=15.51, MSe=.03, p < .0002 \), which increased until in the high-complexity scenario, manipulations occurred once per minute.

At the other extreme, PREQ or CQUERY were relatively rare, never reaching over 4% of the recorded events, and not revealing any significant changes with complexity.

**Transition analyses**

A 7 x 7 matrix of transitions from one event to another was computed for each subject, normalized by dividing by the total number of events, and weighted by the temporal separation between events. The temporal weighting was accomplished in the following way. When compiling the frequency of transitions, the increment to the frequency count was a negative exponential function of the elapsed time. Specifically, the time-weighting function was:

\[
I = e^{-k}
\]

where \( s \) refers to the number of seconds between the two events and \( k \) is a decay parameter, with larger values of \( k \) corresponding to more rapid decay, or increasingly less impact from more time-distant events. The increment \( I \) was used as the increment to the transition count. All analyses used a value of \( k \) of 0.1, which yielded a time-weighting function of the desired characteristics. Thus, two events that occurred simultaneously \( (s = 0) \) would produce an increment of unity \( (I = 1) \), one that occurred by 1 second would be given an increment of .90, and so on. Sequential events separated by 20 s (or more) contribute little to the transition count between those two events \( (I = .13) \). All analyses to be reported were conducted on these normalized and time-weighted transition matrices. Inter-observer reliability for these transition matrices ranged between .75 and .90.

![Table 2](image)

*Table 2. The number of individual transition matrices most highly correlated with each group transition matrix.*

suggesting that the medium-complexity scenarios shared properties of both the low- and high-complexity scenarios. This lack of uniqueness for the medium-complexity level scenario manifested itself in other analyses.

**Pathfinder**

The normalized and time-weighted transition matrices were submitted to the Pathfinder algorithm. The algorithm produces a network where the communication events and the FPS events are represented by nodes and the transitions are represented by arcs between the nodes. The weight of the arc reflects the frequency with which that transition occurred.

The particular application of Pathfinder that we used was one guaranteed to produce the simplest network, the minimal cost network (MCN). The mean 7 x 7 transition matrices were submitted to the Pathfinder algorithm for each of the three levels of complexity. The resultant MCNs appear in Figure 2. The arcs were supplied by
Figure 2. Minimal cost networks (MCNs) for low (top), medium (middle), and high (bottom) complexity. Size of the nodes reflects the proportion of times that event occurred. Transition is represented by an arrow (arc) from one node to another. Thickness of the arcs reflect the proportion of times that transition occurred.
Pathfinder and the width of the arcs reflects the weight of the transition, with thick arcs having occurred proportionately more often than thin arcs. The figures are further augmented by the proportional frequencies of occurrence of the events as represented by the size of the nodes. Events that occurred proportionately more often are represented by larger nodes. Note that in contrast to multi-dimensional scaling solutions, in Pathfinder networks the physical distances between nodes in the depiction is meaningless. All that matters is whether the nodes are linked or not, the direction of the arc, and how “strong” that arc is.

Visual inspection of the MCNs reveals that all of the networks are greatly simplified compared with the original input matrices, which contained 49 transitions. The graphs also look remarkably similar, both qualitatively and quantitatively. Qualitatively, a number of arcs appear in all three networks. Quantitatively, often-traveled arcs (thick lines) in one network tend to appear in the others. In fact, the medium-complexity MCN contained only one arc (a pilot request loop) not present in either the high or low-complexity MCN. As in the individual-to-group correlations, we see that the graph representations of the medium-level scenarios were composites of both the high and low-complexity scenarios.

Computation of various graph-theoretic measures (see Table 3) confirms that, at least at a macroscopic level of analysis, the networks are quite similar. The networks have a comparable number of arcs, and the most distant path (the diameter) of each network is similar with perhaps the low-complexity network being slightly less compact.

Table 3. Global MCN Characteristics
Centrality

The nodes also seem to play similar graph-theoretic roles in the three networks. For example, WRITE plays a central role in all three networks. Table 3 also reports three different measures of centrality for both the incoming transitions (prestige) and the outgoing transitions (influence).

Prestige. A node that receives a large number of arcs, or that serves as a central location for incoming arcs, is said to have prestige. One measure of prestige is the in-degree, a simple count of the number of arcs terminating on a node. Another measure of this type is the in-center, the node that minimizes the distance to the farthest node. A final measure of prestige is the in-median. This measure minimizes the distance to all the nodes. Interestingly, the WRITE node appears to be the most prestigious regardless of the complexity of the scenario. In part this may be the result of the mandatory strip marking done for legal purposes.

Influence. Influence measures reflect the centrality of the node in terms of the number of outgoing transitions. Thus the out-degree is a simple count of the number of arcs leaving a node, the out-center is the node that minimizes travel from that node to the most distant node, and the out-median is the node that minimizes travel to all the nodes. All three measures of centrality are important. The node that minimizes influence is the one that is most central to the network. It is also the node that is most likely to be affected by changes in the network. For example, if the node that minimizes influence is removed from the network, the network will be disrupted and it will take longer for the network to recover. Therefore, it is important to identify the node that minimizes influence in order to protect it from any potential disruptions.
Comparing across complexity

Consideration of the intersection of the three graphs revealed a number of transitions that were fundamental to the way in which controllers operated. Figure 3 shows the arcs common to the three networks. Nine arcs are shared by all three, thus 56% of the arcs in the low-complexity and medium-complexity networks are fundamental, and 60% of the arcs in the high-complexity network are fundamental.

There were two loops fundamental to the scenarios: a CCOM loop and a MANIP loop, with the former being much more substantial than the latter in all three scenarios. The loops indicate that the controllers often followed one controller command with another and one manipulation with another. Controller commands followed controller commands about as often in the low-complexity scenario as in the high. For manipulations, on the other hand, not only did they occur at a higher rate overall in the more complex scenarios (see Figure 1), they tended to follow other manipulations slightly more often in the high-complexity scenarios. In addition to agreement on the two loops, the three networks agreed on bidirectional transitions between CCOM and WRITE, and between SECTOR and WRITE. Each of the networks also had transitions between WRITE and MANIP, between WRITE and LOOK, and between PREQ and CCOM. Thus, across complexity several important transitions appear to be fundamental to the control of air traffic.

The MCNs of the high and low complexity also differed in a number of interesting ways. These differences can supply insight into how controllers interact with strips differently depending on the complexity of the air traffic situation. We turn now to these differences.

One of the most frequent interactions between a communication event and FPS activities is captured in the arcs between CCOM and WRITE. This likely reflects in part the role of the FPS as a legal record. The fact that complexity affects this interaction is evident: As complexity increased, the frequency of the transition from CCOM to WRITE decreased. It is important to note that controllers do not write less in the complex scenarios. On the contrary, the sizes of the nodes for WRITE are virtually identical across the three scenarios (see also Figure 1). What does change as a function of complexity, however, is when writing takes place. As complexity increases, the controllers no longer use a command as a departure point for updating the strips. An implication of this phenomenon is that in a high-complexity traffic situation, the controller will begin to fall behind in his or her updating of strip information. In fact, whereas the CCOM to WRITE arc becomes less prominent in the high-complexity scenario, a CCOM to LOOK arc emerges, suggesting that controllers must now settle for a look toward the bay. Being unable to record information on the strips as it is acquired may have other consequences. For example, it appears that controllers now engage in a series of controller queries (the CQUERY loop) in the high-complexity scenario. There may be too many aircraft for the controller to remember all the altitudes, speeds, and headings, and because the current information has not been written on the strips, the controller may need to ask the pilot to provide that information, which adds further to the workload.

Although each network showed a WRITE to MANIP arc, it is apparent that the frequency of this transition increased with complexity, mirroring the decrease with complexity shown by the CCOM to WRITE arc. Not only does the transition from WRITE to MANIP become more prominent with increasing complexity, an arc from MANIP to WRITE emerges in the high-complexity scenario, presumably replacing the arc from MANIP to CCOM found in the low. Apparently, in high-complexity situations, the controller engages in periods of uninterrupted interaction with the FPSs, whereas in low-complexity situations, the management of the strips is more integrated into the control of traffic. This tendency to engage in uninterrupted board management as complexity increases also helps explain why controllers were much less likely to write on a strip immediately after issuing a command in the high-complexity scenario than they were in the low.

It is intriguing that in the low-complexity scenario, the LOOK node is structurally similar to the MANIP node from the high-complexity scenario; that is, in the
low scenario, LOOK has a loop and connects to the network only through WRITE. It is tempting to speculate that looking serves the Board Management function in less dense traffic situations, whereas looking is replaced, or at least augmented, by manipulating (e.g., moving, offsetting) in the more dense traffic situations.

If controllers are more likely to engage in uninterrupted board management as the Pathfinder analysis suggests, then we should find, in the original data, more frequent sequences of board management activity in the high-complexity scenarios than in the low-complexity scenarios. An analysis of higher-order clusters was performed, which tabulated the frequency of occurrence of all triples and quadruples terminating in an FPS activity across the data for all subjects. An n-tuple was defined as any sequence of N events that occurred together within a 10-second window and that ended in an FPS activity. Ninety-three percent of these clusters involved writing, supporting our assertion that WRITE is the most prestigious and influential of the nodes in the Pathfinder solutions. The clusters support the assertion that controllers adapt to high-complexity situations by partitioning the board management duties into an activity separate from the remaining responsibilities. None of the low-complexity nor the medium-complexity triples exclusively involved writing and manipulating, but 19% of the high-complexity triples did. With regard to four-tuples of activities, the five most frequent four-tuples in the high-complexity scenarios did not involve any CCOM, suggesting again that controllers devote more uninterrupted times to FPS board management in the high-complexity scenario, and relatively less uninterrupted time to communication activity.

DISCUSSION

By observing controllers in situations of varying traffic complexity, it was possible to discover the relationships between communication events and strip activity. This was done by applying the Pathfinder scaling algorithm to matrices of the average transitions between events. Several aspects of air traffic control were shown to generalize to all levels of complexity, including the central role that writing on the strips plays in the current system.

It was also possible to delineate those aspects of air traffic control that tended to change as a function of the traffic complexity. Changes due to complexity applied to all controllers, indicating that individual differences were minor relative to situational factors. Moderate levels of complexity proved to be a composite of low-complexity and high-complexity.

The clearest difference between low-complexity and high-complexity air traffic situations was in the manipulation of the strips. At higher complexity, manipulations occurred at a higher rate, tended to occur with other board management functions, and were less integrated with communication events. The pattern of findings implies that board management is affected by the complexity of the scenario. In the more complex scenarios, the controller is forced to find time to keep the board configured and updated, and he or she does this in concentrated time segments. During these times, controllers may feel that they have “been taken away” from the PVD and the traffic situation. In this sense, the individual controller temporarily divorces from the radar to perform board management duties, essentially serving as his or her own D-side. Fortunately, with a traffic situation as complex as that found in our complex scenario, these D-side, board management duties would normally be performed by a different individual, sparing the controller from the schism of switching from R-side to D-side. In fact, several of controllers indicated the need for a D-side during the high-complexity scenario.

In contrast, while controlling simpler traffic situations the controller could manage the board as an integral part of controlling air traffic. That is, he or she more effectively time-shared between controlling traffic and managing the board: Strips were updated immediately after issuing a command and board management was integrated with other controller activities.

This result implies that automation may in fact facilitate control in higher-complexity situations if it allows the computer to take responsibility for the, now apparently segregated, board management duties. This is a very viable outcome of automation. However, an unwanted by-product of automation may be an increased workload in other areas (e.g., more keyboard-intensive)
which may offset any advantage gained from having the computer take over board management duties. Nevertheless, it is likely that any facilitating effects of automation will be more pronounced in more complex situations, and that controllers in those situations would be better able to control traffic without the assistance of a D-side if the automation truly allows the controller to integrate board management duties with traffic separation.

FINDINGS

- Writing is central. Much of ATC activity is organized around this activity. Because automation will affect this hub of ATC activity, it should substantially impact controller performance. Whether it has a positive or negative impact awaits the final design of the system and additional research.

- Board management is segregated from controlling traffic as traffic complexity increases. Automation may facilitate control in higher-complexity situations if the computer takes control of the segregated board management duties. However, if automation increases board management workload (more keyboard intensive), it may offset any advantage gained by automation.
